Closure between HALO measured CCN(S), cloud base updraft and cloud droplets concentration

During CHUVA-ACRIDICON campaign over the Amazon basin the HALO aircraft measured the spectra of CCN(S), cloud base updraft (W) and droplets concentration (Nd). Since the combination of CCN(S) and W determine Nd and the supersaturation (S), we could calculate the consistency between the measured and theoretical relationships among these measurements. However, W and Nd have large variability along a cloud pass. We have to find the statistical representation of the range of values of measured W and Nd that fulfill best the closure. For example, our previous studies showed that $W^* = \frac{\int W^2}{\int W}$ represents best the integrated properties of the cloud drops. Predicting $Nd^*$ by application of $W^*$ to the measured CCN(S) matches best the 66th percentile of the measured Nd, which is defined as $Nd^*$.

Characterizing the CCN(S) and the cloud by $W^*$ and $Nd^*$ provides a fairly complete description of its base properties. Using $Nd^*$ is useful for identifying which of the measured Nd from the various instruments that measured it is likely to be closest to the true value. $W^*$ and $Nd^*$ are useful for both validating explicit cloud models and parameterizing models that cannot resolve the individual clouds.
